### **Background**

Assessment of regional ventricular deformation is more sensitive than ejection fraction (EF) for detecting myocardial dysfunction. We sought to compare a local sinewave modelling (SinMod) method with the more established harmonic phase analysis (HARP) technique, for assessment of Lagrangian left ventricular (LV) peak systolic circumferential strain ( $\epsilon$ cc) from tagged cardiovascular magnetic resonance images, in patients with cardiomyopathies and healthy volunteers. The variability and rapidity of each technique, and the effect of contrast, were also assessed.

### **Methods**

Sixty participants (15 each with hypertrophic, dilated or ischaemic cardiomyopathy and 15 healthy controls) with a wide range of LV ejection fraction (14-78%) underwent spatial modulation of magnetization tagging of a mid-ventricular short-axis slice at 1.5 Tesla. Global and segmental peak transmural ECC were measured using HARP and SinMod. Repeated measurements were performed on 15 randomly selected scans (25%) in order to assess observer variability. Tagged images were acquired pre- and post-contrast in 10 additional patients in order to assess the effect of contrast.

### **Results**

There was a high level of agreement between HARP and SinMod for global Ecc (mean difference -0.02, 95% limits

of agreement -6.46 to 6.43%, Figure 1). Agreement was much lower for segmental &cc, ranging from poor in lateral segments to modest in inferoseptal segments. Both methods showed excellent inter- and intraobserver agreement for global &cc (intraclass correlation coefficient>0.75). Inter- and intraobserver agreement for segmental &cc were also excellent with SinMod, and were significantly better than with HARP (p<0.0005, Figure 2). SinMod analysis time was significantly shorter than that for HARP (84±42 versus 201±120 seconds, p=0.02). Pre- and post-contrast global and segmental &cc measurements were not significantly different using either technique, although post-contrast measurements showed greater variability with HARP.

### **Conclusions**

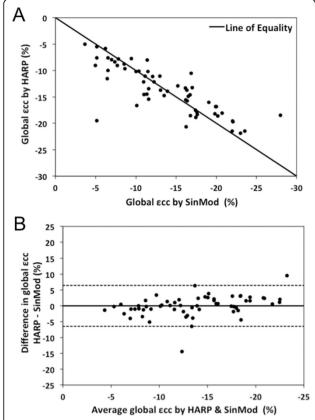

SinMod and HARP-based measurements of global  $\varepsilon cc$  have a high level of agreement. Agreement is substantially lower for measurement of segmental  $\varepsilon cc$ . The Sin-Mod method has generally lower observer variability, is faster and is less affected by contrast.

### **Funding**

Dr Miller was supported by a Doctoral Research Fellowship from the National Institute for Health Research, UK (NIHR-DRF-2010-03-98). Dr Schmitt was supported by Greater Manchester Comprehensive Local Research Network funding. Dr McCann and Dr Steadman received support from the NIHR Leicester Cardiovascular Biomedical Research Unit and additionally, Dr Steadman was funded by the British Heart Foundation (PG/07/068/2334).

**Figure 2** Interobserver and intraobserver variability for measurement of global and segmental peak systolic circumferential strain (εcc) using local sine-wave modelling (SinMod) and harmonic phase (HARP) analysis methods. Variability (calculated as 1 - intraclass correlation coefficient [ICC]) is greater for segmental εcc measurements than for global strain measurements using both techniques. SinMod had significantly lower intraobserver variability than HARP for measurement of global εcc. SinMod also had significantly lower inter- and intraobserver variability than HARP for pooled segmental εcc measurements. Ant - anterior segment, AntLat - anterolateral segment, InfLat - inferolateral segment, Inf - inferior segment, InfSep - inferoseptal segment, AntSep - anteroseptal segment, Pooled - pooled segmental analysis. \* denotes a significant difference, assessed using a Wilcoxon rank comparison of the squared differences (p<0.05).

# Submit your next manuscript to BioMed Central and take full advantage of:

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution
